Many real oscillators are coupled to other oscillators and the coupling can affect the response of the oscillators to stimuli. We investigate phase response curves (PRCs) of coupled oscillators. The PRCs for two weakly coupled phase-locked oscillators are analytically obtained in terms of the PRC for uncoupled oscillators and the coupling function of the system. Through simulation and analytic methods, the PRCs for globally coupled oscillators are also discussed.

Many systems in physics, chemistry and biology are modeled as interacting nonlinear oscillators [1, 2, 3, 4, 5, 6]. One of the easiest ways to characterize an oscillator is its phase response curve (PRC)[3, 4, 5, 6, 7]. The PRC is defined as the steady phase shift of an oscillation relative to the unperturbed oscillation as a function of the timing of perturbation to the oscillator. It provides a useful information for understanding the oscillator's behavior when the oscillator is subjected to external stimuli or signals from other oscillators.

In most of previous studies, the PRC is obtained when the oscillator is isolated from other oscillators [3, 4, 5, 7]. However, many oscillators in real systems are coupled to others when they are under the influence of external stimuli, and the coupling can affect the response of the oscillators. To better understand the dynamics of oscillators such as the response of neuronal population to signals from other brain region [5] or to controlling stimulations [6], it is necessary to study how the coupling changes the PRCs. This study can also give insights into the phase response of a giant oscillator (for example, circadian rhythm generators [3]) composed of many individual oscillators [8]. In this letter, we study the PRC of coupled oscillators using the average phase of the system and the relative phases between the oscillators comprising the system. The PRC is shown to depend on the PRC of the isolated oscillator, the nature of the coupling, and the relative phases between the oscillators. For some cases, the PRCs are analytically obtained. Our approach differs from that of Ref. [8] in that we analytically approximate the PRC while they require the numerical evaluation of the adjoint of a certain linear operator.

If coupling between a network of oscillators is sufficiently "weak", the possibly high-dimensional system can be reduced to a network of coupled phase models [2, 4, 5]. In the following we exploit this fact and restrict our analysis to coupled phase models. Consider, first, two weakly coupled phase-locked oscillators subjected to a common perturbation characterized by their individual PRC:

$$\dot{\theta}_1 = \omega_1 + KH(\theta_2 - \theta_1) + Z(\theta_1) \cdot A\delta(t - t_1), \quad (1)$$
$$\dot{\theta}_2 = \omega_2 + KH(\theta_1 - \theta_2) + Z(\theta_2) \cdot A\delta(t - t_1), \quad (2)$$

where $\theta_i(t)$ is the phase of oscillator i at time t, ω_i is the natural frequency of the oscillator i and $K(\geq 0)$ is the coupling strength. $H(\theta)$ is the coupling function obtained by the phase reduction [2, 4, 5]. $A\delta(t - t_1)$ denotes a Dirac delta impulse with amplitude A at time t_1 which is sufficiently large so that the perturbing impulse is applied after the system reaches a steady state. $Z(\theta)$ is the PRC for uncoupled oscillator obtained using an impulse with unit amplitude. Without coupling ($K = 0$), the impulse causes steady phase shift $AZ(\theta_i(t_1))$ for oscillator i.

In the presence of coupling ($K \neq 0$), if the oscillators are locked with nonzero phase difference, or the input amplitudes are different, then the input impulse generally causes nonidentical phase changes to the oscillators. Thus, the system transiently deviates from the locked state and then returns to the state. The coupling can affect the phase shift which the oscillation of the recovered state can have relative to the unperturbed oscillation. We wish to determine the PRC of the coupled oscillators, in other words, how the phase shift depends on the phase at t_1 of the perturbation.

To analyze the dynamics, we convert Eqs. (1) and (2) into those for the average phase $\Phi \equiv \frac{\theta_1+\theta_2}{2}$ and the relative phase $\phi \equiv \theta_1 - \theta_2$.

$$\dot{\Phi} = \bar{\omega} + KH_e(\phi) + Z_{av}(\theta_1, \theta_2) \cdot A\delta(t - t_1), \quad (3)$$
$$\dot{\phi} = \Delta\omega - 2KH_o(\phi) + Z_d(\theta_1, \theta_2) \cdot A\delta(t - t_1), \quad (4)$$

where $\bar{\omega} = \frac{\omega_1+\omega_2}{2}$, $\Delta\omega = \omega_1 - \omega_2$, $Z_{av}(\theta_1, \theta_2) = \frac{Z(\theta_1)+Z(\theta_2)}{2}$, $Z_d(\theta_1, \theta_2) = Z(\theta_1) - Z(\theta_2)$, $H_e(\phi) = \frac{H(\phi)+H(-\phi)}{2}$, and $H_o(\phi) = \frac{H(\phi)-H(-\phi)}{2}$.

For simplicity, let us assume that the system has one stable locked state with $\phi = \phi_0$ satisfying $0 = \Delta\omega - 2KH_o(\phi_0)$ and ${H_o}'(\phi_0) > 0$. The phase of each oscillator can be written as $\theta_1 = \Phi + \phi/2$ and $\theta_2 = \Phi - \phi/2$. Let us denote the phase shift in a phase, for example θ_1, relative to the unperturbed oscillation by $\Delta\theta_1$. We can see that the phase shift for the oscillator 1 is given by

$$\Delta\theta_1 = \Delta\Phi + \Delta\phi/2. \quad (5)$$

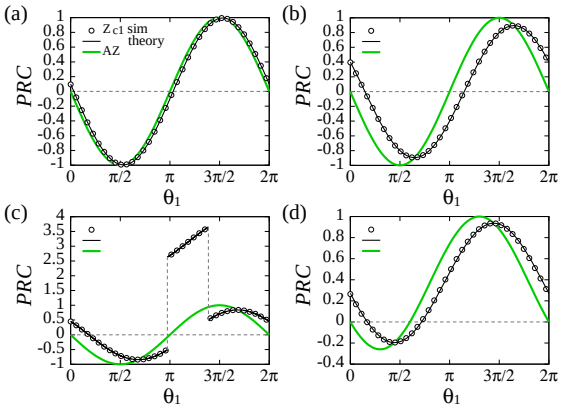

FIG. 1: (Color online) PRCs with odd coupling functions. $\omega_1 = \pi/2 + \Delta\omega$ and $\omega_2 = \pi/2$. $\Delta\omega = 0.4$ and $A = 1$. (a) $K = 1$: $\phi_0 \approx 0.201$. (b) $K = 0.25$: $\phi_0 \approx 0.927$. (c) $K = 0.22$: $\phi_0 \approx 1.141$. For (a), (b), and (c), $H(\theta) = \sin\theta$ and $Z(\theta) = -\sin\theta$. (d) $H(\theta) = \sin\theta - 0.4\sin(2\theta)$, $Z(\theta) = -[\sin(\theta + 0.2\pi) - \sin(0.2\pi)]/[1 + \sin(0.2\pi)]$, and $K = 0.5$: $\phi_0 \approx 0.908$.

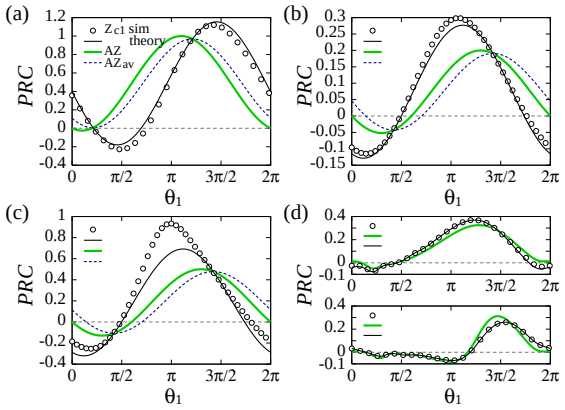

FIG. 2: (Color online) PRCs with non-odd coupling functions. For (a)-(c), $\omega_1 = \pi/2 + \Delta\omega$, $\omega_2 = \pi/2$ and $\Delta\omega = 0.4$. (a) $H(\theta) = \sin(\theta + 0.4\pi)$, $Z(\theta) = -[\sin(\theta + 0.4\pi) - \sin(0.4\pi)]/[1 + \sin(0.4\pi)]$, and $K = 1$: $\phi_0 \approx 0.704$, $A = 1$. (b) $H(\theta) = \sin(\theta - 0.4\pi) + 0.3\sin(2\theta - 0.1\pi)$, $Z(\theta) = -[\sin(\theta + 0.2\pi) - \sin(0.2\pi)]/[1 + \sin(0.2\pi)]$, and $K = 0.4$: $\phi_0 \approx 0.769$, $A = 0.2$. (c) $H(\theta)$, $Z(\theta)$, and K are the same as in (b) : $\phi_0 \approx 0.769$, $A = 0.5$. (d) gap-junction coupled Morris-Lecar oscillators [4]: $I_{ext,1} = I_0 + \Delta I$ and $I_{ext,2} = I_0 - \Delta I$ with $\Delta I = 0.2$, $A_V = 40$. (top) type I case, $I_0 = 50$ and $g_{syn} = 0.015$, $\phi_0 \approx 1.279$. (bottom) type II case, $I_0 = 94$ and $g_{syn} = 0.01$, $\phi_0 \approx 0.778$.

When $H(\theta)$ is an odd function, the average phase Φ evolves with a constant frequency $\bar{\omega}$ before and after the impulse (Eq. (3)). Thus, $\Delta\Phi = AZ_{av}(\theta_1(t_1), \theta_2(t_1))$. When the relative phase remains in the basin of attraction of the original relative phase right after the impulse, ϕ approaches the original relative phase. Otherwise, the relative phase moves to another stable value (called walk-through). Thus, $\Delta\phi = \phi_f - \phi_0$, where ϕ_f is the stable value of ϕ reached after the impulse. Note that even $\phi = \phi_0$ and $\phi = \phi_0 + 2\pi$ give different results. Therefore, the PRC of the oscillator 1 in the coupled cases is given by

$$Z_{c1}(\theta_1) = AZ_{av}(\theta_1, \theta_1 - \phi_0) + (\phi_f - \phi_0)/2. \qquad (6)$$

We simulate Eqs. (1) and (2) using Euler method with time step $\Delta t = 0.01$. We measure the steady phase shift due to the impulse relative to the unperturbed activity. The PRC is given by this phase shift as a function of the phase at which the impulse is applied.

Figure 1 shows $Z_{c1}(\theta_1)$ with odd coupling functions. The prediction from the theory (black solid curves) matches very well with the simulation results (symbols). With larger values of $\Delta\omega$ and/or smaller values of K, the oscillators are locked with larger ϕ_0. In Figs. 1(a), (b), and (c) with $H(\theta) = \sin\theta$ and $Z(\theta) = -\sin\theta$, we show the PRC for different values of the coupling strength K. When ϕ_0 is very small, the PRC of coupled oscillators is very close to that of uncoupled oscillators as expected (Fig. 1(a)). In this case, ϕ goes to the original value ϕ_0 after the impulse. In Fig. 1(b), with the larger ϕ_0, the PRC of the coupled oscillator becomes significantly different from that of uncoupled oscillators. When the impulse can kick the system out of the basin of the stable locked state with ϕ_0, the system goes through phase walk through. If the system has a stable fixed point with ϕ_0 and an unstable fixed point ϕ_u in $[0, 2\pi)$ as in the case with $H(\theta) = \sin\theta$ for $\Delta\omega < 2K$, ϕ_u has the role of basin boundary and ϕ goes to $\phi_f = \phi_0 + 2\pi$ when $\phi_0 + AZ(\theta_1(t_1)) - AZ(\theta_2(t_1)) > \phi_u$. This type of changes in ϕ causes the discontinuity shown in the PRC of Fig. 1(c). We show similar results for a coupling function with higher order Fourier terms and an asymmetric PRC (Fig. 1(d)).

When $H(\theta)$ is not an odd function, the even part of H affects the dynamics of Φ and thus the phase shift $\Delta\Phi$ through Eq. (3). Finding the PRC in the analytic form is not possible for these cases since we have to solve equation (4) for general initial data. Instead, we can get an approximation of the PRC in the limit of small changes in ϕ. Let $\phi = \phi_0 + q$ with $|q| \ll 1$. We can linearize Eq. (4) and obtain approximation $q \approx q_0 e^{-2KH_o'(\phi_0)(t-t_1)}$ for $t > t_1$ where q_0 is the change in ϕ right after the impulse: $q_0 = AZ_d(\theta_1(t_1), \theta_2(t_1))$. As $t \to \infty$, ϕ returns to ϕ_0. Thus, $\Delta\phi = 0$. The phase shift $\Delta\Phi$ is given by $\Delta\Phi = AZ_{av}(\theta_1(t_1), \theta_2(t_1)) + \int_{t_1}^{\infty} K\,[H_e(\phi) - H_e(\phi_0)]\,dt \approx AZ_{av}(\theta_1(t_1), \theta_2(t_1)) + \frac{H_e'(\phi_0)}{2H_o'(\phi_0)} q_0$, where we use $H_e(\phi) - H_e(\phi_0) \approx H_e'(\phi_0) q(t)$.

Therefore, the PRC of the oscillator 1 is

$$Z_{c1}(\theta_1) \approx AZ_{av}(\theta_1, \theta_1 - \phi_0) + \frac{H_e'(\phi_0)}{2H_o'(\phi_0)} AZ_d(\theta_1, \theta_1 - \phi_0). \qquad (7)$$

Figure 2 shows $Z_{c1}(\theta_1)$ with non-odd coupling functions. In Fig. 2(a), we show the PRC with the simple type of H. While AZ and AZ_{av} are similar, the

obtained PRC for the coupled oscillator is significantly different from them. The curve from Eq. (7) fits well with simulation results for the entire range of θ_1. Figure 2(b) shows the results with a H function with higher order terms. We use small $A = 0.2$ for this case and the PRC from the theory fits well with the simulation result. In Fig. 2(c), we use the same parameters as in (b) except $A = 0.5$. With the larger A, the theory mismatches significantly for a range of phases, but still gives a relatively similar shape to the simulations. The overall matching is due to the fact that $q = 0$ at some phases satisfying $Z(\theta) = Z(\theta - \phi_0)$ and around those phases the theory fits well with simulation results. Figure 2(d) shows the PRC of gap-junction coupled Morris-Lecar oscillators with slightly different injection currents [4]: $C\dot{V}_i = -I(V_i, w_i) + I_{ext,i} + g_{syn}(V_j - V_i) + A_V\delta(t - t_1)$ with $j = 2, 1$ for $i = 1, 2$. The details are in Ref. [4]. The system is simulated using the 4th-order Runge-Kutta method. For type I and type II cases, the theory gives good fitting with the simulation results with weak stimulus.

Next, we want to understand PRCs for oscillators coupled to many other oscillators. We study the case with globally coupled oscillators: For $i = 1, 2, ..., N$,

$$\dot{\theta}_i \;=\; \omega_i + \frac{K}{N}\sum_{j=1}^{N} H(\theta_j - \theta_i) + Z(\theta_i)\cdot A\delta(t - t_1), \quad (8)$$

where N is the total number of oscillators and others are as defined in the two oscillator system.

We introduce similar variables as in two coupled oscillators: the average of the phases $\Phi \equiv \frac{1}{N}\sum_{j=1}^{N}\theta_j$ and the phase $\phi_i \equiv \theta_i - \theta_M$ of oscillator i relative to the phase of oscillator M, where the subscript M denotes the oscillator which has the average frequency $\bar{\omega}$. From the definitions of Φ and ϕ, we obtain $\theta_M = \Phi - \frac{1}{N}\sum_{j=1}^{N}\phi_j$. Because the PRC for other oscillators can be treated similarly and oscillator M follows closely to the collective behavior of the system, we focus on the PRC $Z_c(\theta_M)$ of oscillator M. As in the case of two coupled oscillators, we get

$$Z_c(\theta_M) \;=\; \Delta\Phi - \langle\Delta\phi\rangle \text{ with } \langle\Delta\phi\rangle \equiv \frac{1}{N}\sum_{j=1}^{N}\Delta\phi_j. \quad (9)$$

The equation for Φ is

$$\dot{\Phi} \;=\; \bar{\omega} + \frac{K}{N^2}\sum_{i,j=1}^{N} H_e(\phi_j - \phi_i) + Z_{av}\cdot A\delta(t - t_1), \quad (10)$$

where $Z_{av}(\theta_1, \ldots, \theta_N) \equiv \frac{1}{N}\sum_{i=1}^{N} Z(\theta_i(t))$.

For an odd function $H(\theta)$, $\Delta\Phi = AZ_{av}$. But for a non-odd function $H(\theta)$, the second term contributes to $\Delta\Phi$ and it is not easy to calculate $\Delta\Phi$ analytically.

Let us consider fully locked states first. For a fully locked state with relative phases ϕ_{i0}, the system returns to the locked state after the stimulation and the relative phase ϕ_{i0} can be changed to the equivalent phase $\phi_{i0} + 2n_i\pi$, where n_i is an integer. Thus, $\Delta\phi_i = 2n_i\pi$.

With $H(\theta) = \sin(\theta + \beta)$, which is a good approximation for many general coupling functions, Eq. (8) becomes

$$\dot{\theta}_i \;=\; \omega_i + KR\sin(\Theta - \theta_i + \beta) + Z(\theta_i)\cdot A\delta(t - t_1), \quad (11)$$

where R and Θ are the order parameter and the corresponding collective phase respectively defined by $Re^{i\Theta} \equiv \frac{1}{N}\sum_{j=1}^{N} e^{i\theta_j}$. In the frame rotating with the synchronization frequency Ω, the equation becomes

$$\begin{aligned}\dot{\psi}_i \;&=\; \omega_i - \Omega + KR\sin(\tilde{\Theta} - \psi_i + \beta) \\ &\quad + Z(\theta_i)\cdot A\delta(t - t_1), \end{aligned} \quad (12)$$

where $\psi_i \equiv \theta_i - (\Omega t + \Theta_0)$, $\tilde{\Theta} \equiv \Theta - (\Omega t + \Theta_0)$ and the constant Θ_0 is chosen such that the stationary value of $\tilde{\Theta}$ before the impulse is zero. Let R_0 denote the stationary value of R. We can analyze the stationary state of the system, using self-consistency argument and find R_0 and Ω [2, 9].

For fully locked states or partially locked states where the oscillator M is locked with a locking phase ${\psi_M}^*$ and the oscillators form a stationary distribution relative to the frame rotating with Ω, $Z_{av} = \frac{1}{N}\sum_{i=1}^{N} Z(\theta_M + \psi_i - {\psi_M}^*)$, where ${\psi_M}^* = \sin^{-1}(\frac{\bar{\omega} - \Omega}{KR_0}) + \beta$. For $Z(\theta) = a_1 + a_2\sin(\theta + \xi)$, using $R_0 = \frac{1}{N}\sum_{j=1}^{N} \mathrm{e}^{\mathrm{i}\psi_j}$, we obtain

$$Z_{av} \;=\; a_1 + a_2R_0\sin(\theta_M + \xi - {\psi_M}^*). \quad (13)$$

Note that since $R_0 < 1$, the magnitude of the sinusoidal part of Z_{av} is smaller than that of Z unless synchrony is perfect.

Figures 3(a)-(e) show results with $H(\theta) = \sin\theta$ and a uniform distribution for the frequencies of the oscillators. We use $Z(\theta) = -\sin\theta$ for (a)-(d), and an asymmetric $Z(\theta)$ for (e). With the given coupling strength, the system shows a fully locked state (Fig. 3(a)). Figures 3(b) and (c) show the PRCs for different values of A. With weak stimulation (Fig. 3(b)), all ϕ_i return to the unperturbed values ($\Delta\phi_i = 0$ for all i, Fig. 3(d)) and the PRC is shown to be contributed only by $\Delta\Phi = AZ_{av}$. The prediction $Z_c(\theta_M) = AZ_{av}$ from the theory (Eq. (13)) fits well with the simulation results. In contrast, with a stronger impulse (Fig. 3(c)), the simulation results deviate from $Z_c(\theta_M) = AZ_{av}$ for some range of θ_M. We calculate $\langle\Delta\phi\rangle$ from the simulations and it accounts for the deviation as predicted from Eq. (9).

The deviation in Fig. 3(c) can be understood as follows. Nonzero $\Delta\phi_i$ can occur only when the order parameter transiently decreases. For $\theta_M \in (\pi/2, \pi)$, the impulse disperses the locked group, because the trailing oscillators receive more negative impact than the leading ones. Thus, the order parameter decreases from R_0 to $R(t_1+)$ ($< R_0$). R can decrease more depending on the behavior of the oscillators, and then returns to R_0. The collective phase Θ also decreases ($\tilde{\Theta}(t_1+) < 0$), because most of the phases of the oscillators decrease due

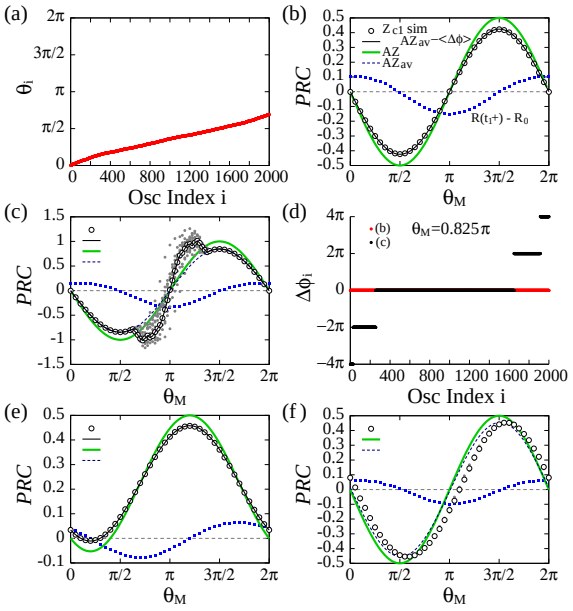

FIG. 3: (Color online) Fully locked cases. (a) snapshot of phases of oscillators: a fully locked state (b) $A = 0.5$. (c) $A = 1.0$. (d) $\Delta\phi_i$ for (b) and (c) with $\theta_M = 0.825\pi$. For (a)-(d), $H(\theta) = \sin\theta$ and $Z(\theta) = -\sin\theta$. (e) $H(\theta) = \sin\theta$, $Z(\theta) = -[\sin(\theta + 0.3\pi) - \sin(0.3\pi)]\,/\,[1 + \sin(0.3\pi)]$, and $A = 0.5$. (f) $H(\theta) = \sin(\theta + 0.1\pi)$, $Z(\theta) = -\sin\theta$, and $A = 0.5$. A uniform distribution is used for $\{\omega_i\}$: (i) $\omega_i = \bar{\omega} - \Delta\omega + \frac{2\Delta\omega(i-1)}{N-1}$ or (ii) randomly selected ω_i from $[\bar{\omega} - \Delta\omega, \bar{\omega} + \Delta\omega]$. (i) is used for the symbols of (a)-(e) except the gray circles in (b), (c), (e), and (f). $\bar{\omega} = \pi/2$. $\Delta\omega = 0.6$. $K = 0.8$ for (a)-(e) and $K = 1$ for (f).

to the impulse. The sudden changes in R and $\tilde{\Theta}$ affect the dynamics of oscillators. The behaviors of oscillators right after the impulse can be described by the equation $\dot{\psi}_i = \omega_i - \Omega + KR(t_1+)\sin(\tilde{\Theta}(t_1+) - \psi_i)$ with $\psi_i(t_1+) = \psi_i{}^* + Z(\theta_M(t_1) + \psi_i{}^* - \psi_M{}^*)$, where $\psi_i{}^*$ is the locking phase for oscillator i. The trajectory of oscillator i can escape completely from the basin of attraction of ϕ_{i0} during the transient behavior of R and settle to the equivalent phases $\phi_i = \phi_{i0} + 2n_i\pi$. Since the curves for $(\psi_i, \dot{\psi}_i)$ are shifted to the left due to the negative $\tilde{\Theta}(t_1+)$ and upwards(downwards) for the oscillators with $\omega_i > \Omega$ ($\omega_i < \Omega$), the oscillators with frequencies far from the average one can escape and those with higher frequencies escape first. Because of this, $\langle\Delta\phi\rangle > 0$ and the PRC deviates negatively from AZ_{av} (Eq. (13)). The oscillators with frequencies far from the average one have more chance to have higher n (Fig. 3(d)), because they can drift faster and stay unlocked longer. Other ranges of θ_M can be understood similarly.

When $H(\theta)$ is not odd, it is difficult to find the general results. For $H(\theta) = \sin(\theta + \beta)$, we can see that the second term of Eq. (10) is equal to $KR^2\sin\beta$. Thus, $\Delta\Phi = AZ_{av} + K\sin\beta\int_{t_1}^{\infty}(R^2 - {R_0}^2)dt$. With weak stimulus, $Z_c(\theta_M) = \Delta\Phi$ and the PRC deviates positively (negatively) from AZ_{av} for values of $R(t_1+) > R_0$ ($R(t_1+) < R_0$) (Fig. 3(f)). The values of $R(t_1+)$ are easily calculable using Z and the distribution for ω.

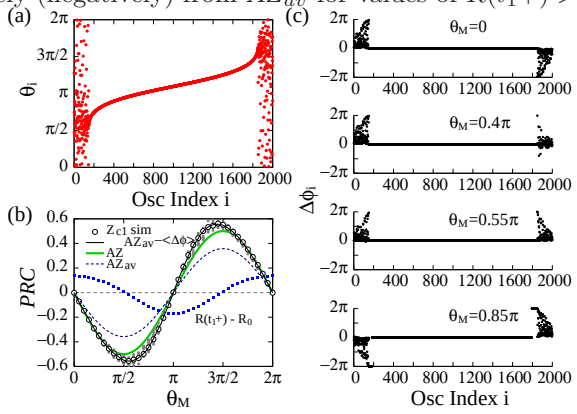

FIG. 4: (Color online) Partially locked cases with $H(\theta) = \sin\theta$. (a) snapshot of phases of oscillators: a partially locked state. (b) $A = 0.5$. (c) $\Delta\phi_i$. $Z(\theta) = -\sin\theta$. $\{\omega_i\}$ obeys a Gaussian distribution $g(\omega, \bar{\omega}) = \frac{1}{\sigma\sqrt{2\pi}}\exp(-\frac{(\omega-\bar{\omega})^2}{2\sigma^2})$: (i) $\omega_{(N/2)+k} = \bar{\omega} + y_k$, $\omega_{(N/2)-k+1} = \bar{\omega} - y_k$ with $y_k = (x_{k-1} + x_k)/2$, $x_{k+1} = x_k + N^{-1}/g(x_k, 0)$, and $x_0 = 0$ for $k = 1, ..., N/2$ [10] or (ii) $\omega_i = \bar{\omega} - y_i$ and $\omega_{i+N/2} = \bar{\omega} + y_i$ with $i \le N/2$ and y_i randomly selected according to $g(y, 0)$ with $y > 0$. (i) is used for the simulations(symbols) of (a)-(c) except the gray circles in (b). $\bar{\omega} = \pi/2$, $\sigma = 0.3$, and $K = 0.6$.

Finally, let us briefly consider partially locked cases in the limit of $N \to \infty$. When the system exhibits a partially locked state, the drifting oscillators form a stationary distribution in the frame rotating with the synchronization Ω. In the original frame, we can say that the distribution rotates with Ω. We can define PRCs for locked oscillators. Let us consider cases with $H(\theta) = \sin\theta$. Figure 4(b) shows the PRC $Z_c(\theta_M)$ of oscillator M for the partially locked state of (a). We can understand $Z_c(\theta_M)$ through Eq. (9). Since H is an odd function, $\Delta\Phi = AZ_{av}$ (Eq. (13)). While for the locked oscillators $\Delta\phi_i = 2n_i\pi$ and is nonzero in some ranges as in the fully locked cases, for the drifting oscillators $\Delta\phi_i$ is usually not an integer multiple of 2π and can be nonzero in any ranges (Fig. 4(c)). Simulations show that $\Delta\phi_i$ for the drifting oscillators contribute significantly to the PRC and the PRC (symbols, Fig. 4(b)) differ from AZ_{av} (the dashed curve) for almost the entire range of θ_M.

In summary, we have investigated the PRCs of coupled oscillators in terms of the PRCs of individuals, the nature of the coupling, and the relative phases of the oscillators. Our approach of obtaining PRCs using the average and relative phases can be applicable to oscillators on different type of networks.
